Abstract: Objectives: In presence of lung cancer, the additional impact of comorbidity on survival is often neglected, although comorbidities are likely to be prevalent. Our study examines the comorbidity profile and the impact of distinct conditions on survival in German lung cancer patients.

Material and methods: We investigated claims data from a large nationwide statutory health insurance fund of 16,202 patients initially diagnosed with lung cancer in 2009. We calculated the prevalence of comorbidities grouped according to an extension of the Elixhauser Comorbidity Index (EI). Effects of distinct comorbidities on 5-year survival were examined using multivariate Cox proportional hazards models, adjusted for sex, age and metastases at baseline. All analyses were stratified by initial lung cancer-related treatment regimen (Surgery, Chemotherapy/Radiotherapy, No treatment). Findings were visualized in the form of a comorbidome. Results: Our study population was predominantly male (70.6%) with a mean age of 68.6 years, and a mean EI score of 3.94. Patients without treatment were older (74.4 years), and their comorbidity burden was higher (mean EI=4.59). Median survival varied by subgroup (Surgery: 24.4 months, Chemotherapy/Radiotherapy: 8.8 months, No treatment: 2.0 months), and so did the comorbidity profile and the impact of distinct conditions on survival. Generally, the effect of comorbidities on survival was detrimental and the negative association was most pronounced for 'Weight Loss' and 'Paralysis'. In contrast, 'Lipid Metabolism Disorders' and 'Obesity' were positively associated with survival. Noteworthily, highly prevalent conditions tended not to show any significant association. Conclusion: We found specific comorbidity profiles within the distinct treatment regimens. Moreover, there were negative but also some positive associations with survival, and the strength of these effects varied by stratum. Particularly the positive effects of 'Obesity" and 'Lipid Metabolism Disorders' which were robust across strata need to be further investigated to elucidate potential biomedical explanations.

Submission to Lung Cancer: "Assessing the Lung Cancer Comorbidome: An Analysis of German Claims Data."

Dear Prof. Dr. Stahel,

Please find enclosed an article, which we would like you to consider for publication in Lung Cancer. The word count of the submitted article is 4,189.

In this paper, we aimed to assess the comorbidity burden in lung cancer patients and its influence on survival. We created comorbidomes to visualize our results. Our analyses are based on data from a large German Statutory Health Insurance (SHI) fund (AOK). We calculated the prevalence of comorbidities according to an extension of the Elixhauser Comorbidity Index. Effects of distinct comorbidities on 5-year survival were examined using multivariate Cox proportional hazards regression models, stratified by initial lung cancer treatment regimen. We found specific comorbidity profiles among the strata. Our results show that lung cancer patients often have a high comorbidity burden and that comorbidities mostly have a detrimental effect on survival. Our analysis not only supports the previously described 'Obesity paradox', but also highlights the crucial role of 'Lipid Metabolism Disorders'. In contrast to other studies, we assessed a very comprehensive set of comorbidities with a long period of follow-up in a representative population of lung cancer patients.

This is the first comorbidome for lung cancer patients in Germany. We do hope you will consider this article for publication in your journal, and we look forward to hearing from you in due course.

We hereby confirm that the given manuscript, including related data, figures and tables has not been published previously and that the manuscript is not under consideration elsewhere. Also, all authors declare no conflicts of interest and have contributed in the conception and design, analysis and interpretation or drafting of the manuscript. All authors have approved the final version of the manuscript.

With thanks and kindest regards

Yours sincerely

Monika Murawski

- The comorbidity burden in lung cancer patients is high
- Prevalence of comorbidities differ by initial lung cancer specific therapy
- As a whole comorbidities only have a minor impact on survival
- Comorbidities associated with shorter survival are mostly of low prevalence
- Obesity is associated with longer survival in lung cancer

20 Abstract

Objectives: In presence of lung cancer, the additional impact of comorbidity on survival is often neglected,
 although comorbidities are likely to be prevalent. Our study examines the comorbidity profile and the
 impact of distinct conditions on survival in German lung cancer patients.

Material and methods: We investigated claims data from a large nationwide statutory health insurance fund of 16,202 patients initially diagnosed with lung cancer in 2009. We calculated the prevalence of comorbidities grouped according to an extension of the Elixhauser Comorbidity Index (EI). Effects of distinct comorbidities on 5-year survival were examined using multivariate Cox proportional hazards models, adjusted for sex, age and metastases at baseline. All analyses were stratified by initial lung cancer-related treatment regimen (Surgery, Chemotherapy/Radiotherapy, No treatment). Findings were visualized in the form of a comorbidome.

31 *Results:* Our study population was predominantly male (70.6%) with a mean age of 68.6 years, and a

mean El score of 3.94. Patients without treatment were older (74.4 years), and their comorbidity burden
 was higher (mean El=4.59). Median survival varied by subgroup (Surgery: 24.4 months,

34 Chemotherapy/Radiotherapy: 8.8 months, No treatment: 2.0 months), and so did the comorbidity profile

35 and the impact of distinct conditions on survival. Generally, the effect of comorbidities on survival was

36 detrimental and the negative association was most pronounced for 'Weight Loss' and 'Paralysis'. In

37 contrast, 'Lipid Metabolism Disorders' and 'Obesity' were positively associated with survival. Noteworthily,

38 highly prevalent conditions tended not to show any significant association.

39 Conclusion: We found specific comorbidity profiles within the distinct treatment regimens. Moreover, there
40 were negative but also some positive associations with survival, and the strength of these effects varied
41 by stratum. Particularly the positive effects of 'Obesity' and 'Lipid Metabolism Disorders' which were
42 robust across strata need to be further investigated to elucidate potential biomedical explanations.

49 1. INTRODUCTION

According to the statistics from GLOBOCAN, about 1.8 million patients were newly diagnosed with lung cancer worldwide in 2012. With 12.9% of all incident cases, lung cancer was the most frequent cancer diagnosis. It was the most common cause of cancer-related death in men and the second common in women [1]. In Germany in 2010, around 35,000 men and 17,000 women were diagnosed with lung cancer [2]. It was the leading cause of cancer-related death in men (25%) and the third leading in women (14%). Despite advances in medical science, most patients still die within the first year of diagnosis, thus lung cancer is of high relevance for public health in Germany [2].

57 Because lung cancer is frequent in the elderly population, and smoking as its main risk factor is also 58 related to other diseases, the additional occurrence of comorbidities is likely [3]. The comorbidity burden 59 in lung cancer patients is higher than in the general population, especially for diseases related to the 60 respiratory tract like COPD, but also for cardiovascular diseases [4]. Within a highly lethal disease like 61 lung cancer, comorbid conditions themselves might be of lower importance for survival prognosis. But, 62 when comorbidities have to be monitored closely by a physician, they might affect survival positively by 63 leading to an earlier detection of the cancer resulting in better treatment options. In contrast, other 64 diseases with similar symptoms may overshadow the lung cancer and thus lead to a later detection. As 65 comorbidities themselves, however, can also affect the choice of treatment or cause complications during 66 therapy, they should not be neglected [5].

67 Several studies investigated the impact of comorbidities on survival in lung cancer patients, resulting in 68 worse prognosis in patients with higher comorbidity burden [6], but, with in details conflicting associations. 69 Since only few studies do not focus on subgroups with distinct cancer types, stages or treatment 70 regimens [7-9], comprehensive knowledge about the associations between comorbidity and survival in 71 lung cancer patients remains scarce. Moreover, there are differing data collection methods and concepts 72 of comorbidity assessment [10], and comorbidity burden often is measured as an aggregated index which 73 was constructed for a specific outcome [11]. Furthermore, patients with high comorbidity burden mostly 74 are excluded from trials, especially in elderly patients [5].

Against this background, the primary aim of this study was to examine the prevalence of a

comprehensive list of comorbidities within a broad population of lung cancer patients and their influence

- 77 on survival. The second aim was to investigate potential differences of distinct conditions between
- 78 different treatment regimens within lung cancer.
- 79 2. MATERIAL AND METHODS
- 80 2.1. SAMPLE SELECTION AND OBSERVATION PERIOD

We analysed claims data from a large German Statutory Health Insurance (SHI) fund (AOK) covering ca. 81 82 30% of the resident population. Data were delivered by the Scientific Institute of the AOK (WIdO) and 83 contained patient-level information on inpatient and outpatient diagnoses from 2007 to 2012. Diagnoses 84 were given according to The International Statistical Classification Of Diseases And Related Health 85 Problems, 10th revision, German Modification (ICD-10-GM). In addition the socio-demographic 86 characteristics sex, age and district area at time of initial lung cancer diagnosis were provided as well as 87 information on 5-year survival. The data was used with ethical consent (ethical vote no. 88-15) and the 88 anonymity of identity was given in any phase of the analysis. 89 The details of the cohort have been described previously [12]. In brief, patients were included if they were

newly diagnosed with lung cancer (ICD-10 code C34) in 2009, aged above 25 and continuously enrolled

91 between 2007 and 2009 (n=17,478).

92 As ICD diagnoses in our dataset were not provided with a precise diagnosis date, the earliest possible 93 date of lung cancer diagnosis was set for each participant based on the first hospital admission date or 94 the begin date of the first outpatient physician case, whichever came first. Records with an overlap of 95 admission and discharge date to the adjacent guarters led to assignment of the lung cancer diagnosis to 96 an earlier quarter. By this, concomitant diagnoses were not appropriately documented within the quarter 97 of lung cancer diagnosis, which therefore led to a misclassification of comorbid conditions within our 98 defined timespan. After exclusion of patients with an overlap, the overall sample size was 16,202 99 patients.

100 2.2. ASSESSMENT OF COMORBIDITIES

As, within the German SHI system outpatient physician services are documented on a quarterly base we looked at comorbidities on a quarterly base. To measure the comorbidities present at baseline, we

included ICD diagnoses from the quarter of the first lung cancer diagnosis and the two quarters prior to diagnosis. In order to be considered, ICDs had to be either inpatient (primary or secondary) diagnoses or outpatient diagnoses documented in two separate quarters. This algorithm corresponds to the morbidityoriented risk structure compensation in the German health system [13]. Outpatient ICD diagnoses in Germany have to be categorized in: 'Z' = condition after, 'A' = exclusion diagnosis, 'V' = suspected diagnosis and 'G' = confirmed diagnosis. To identify relevant outpatient diagnoses we used ICDs marked as confirmed only.

110 Based on claims data and ICD codes, various comorbidity indices and concepts of classification, 111 including adaptions or simplifications, have been established so far [5, 14]. In order to analyse the effect 112 of comorbidities on survival we used the 31 distinct comorbidities defined in the Elixhauser Comorbidity 113 Index (EI), which provides a rather comprehensive set of comorbidity groups [15] and beyond this often 114 showed to outperform other concepts [16, 17]. All relevant diagnoses were summed up in comorbidity 115 groups defined within the EI according to the coding algorithm of Quan et al. [18] implemented in a SAS-116 macro from the University of Manitoba [19]. Due to the nature of our study we excluded lung cancer from 117 the category "Solid Tumor without Metastasis" and the whole comorbidity group 'Metastatic Carcinoma'. 118 Patients diagnosed with both 'Uncomplicated' and 'Complicated Hypertension' or 'Uncomplicated' and 119 'Complicated Diabetes', were assigned to the more severe category. By this, we calculated the El score 120 itself for each patient as the sum of the remaining possible comorbidities, and created four EI score 121 groups according to the empirical distribution within our cohort (group 1: El-score 0-1, group 2: El-score 122 2-3, group 3: 4-5 and group 4: EI-score > 6). 123 Since it was unclear whether the EI fully reflected the comorbidity burden of lung cancer patients, we

additionally looked for high prevalence diagnoses with a high prevalence in the cohort using three-digit ICD-10 codes that are not included in the EI. In this context, we added 'Lipid Metabolism Disorders' (ICD-10 code E78) to the distinct comorbidities.

127 2.3. OUTCOME AND COVARIATES

128 We investigated the effect of comorbidities on all-cause mortality by analysing 5-year survival calculated 129 as time from the date of lung cancer diagnosis to the date of death. Individuals were considered as alive 130 (censored) if death was not reported or if patients lived beyond 1825 days (i.e. 5 years) post diagnosis. 131 As possible confounding variables we considered age and gender as established factors influencing 132 survival. To best control for confounding, we investigated categorizations of age by comparing models 133 with age in years, decades and quartiles. The lowest AIC value and thus the best fit was found for age in 134 years. Metastases were classified as a confounding variable indicating cancer severity, and were defined 135 as ICD-10 codes of C77-C80 following the inclusion criterion of 1 inpatient diagnosis or 2 assured 136 outpatient diagnoses within the quarter of lung cancer diagnosis and the adjacent quarter [12]. 137 Stratification

To approximate cancer stage, we stratified for initial lung cancer-related treatment regimen [12]. Thus, the population was divided into three strata: "Surgery" (SU) for individuals undergoing surgery alone or in combination with chemotherapy or radiotherapy, "Chemotherapy/Radiotherapy" (CH/RA) for those who underwent any of these therapies but no surgery, and "No treatment" (NT) if none of these three treatments was reported. Because the treatment decision is based on both the form of lung cancer and comorbidity, adjusting for the therapy regimen could have led to biased estimates.

144 2.4. STATISTICAL ANALYSIS

In a univariate analysis we compared overall length of survival using Kaplan-Meier plots and log rank
 tests (p≤0.05) for the different El score groups.

147 To examine the association between comorbidities and overall survival, we derived multivariate Cox

148 proportional hazards regression models by forward selection modelling: First, hazard ratios (HR) for the

distinct comorbidities were calculated (adjusted by age, gender and metastases at baseline); then,

150 conditions showing a significant association with survival (p≤0.05) were considered further within the

151 multivariate model. HRs and 95%-confidence intervals (CI) were reported.

152 Similar to previous studies, we visualized our findings in form of a comorbidome, combining the

prevalence of distinct comorbid conditions with their multivariate impact on survival [20, 21]. Within each

treatment regimen, we present a graph of comorbidities with more than 10% prevalence and those with a significant multivariate association with overall survival ($p \le 0.05$) despite of their prevalence.

156 To examine the robustness of our results, two sensitivity analyses were carried out. First, we restricted 157 the identification of baseline comorbidities to the quarter in which the patient was diagnosed with lung 158 cancer, including any inpatient diagnosis or confirmed outpatient diagnosis (SA1). We thereby considered 159 that the results could be driven by timespan of assessment period and the restrictive requirement to 160 outpatient diagnoses. Second, the Bonferroni correction was used to minimize the number of possible 161 false positive results as a problem of multiple testing (SA2). To reduce the concurrent possibility of false 162 rejection of comorbidities within steps of forward selection modelling, the critical limit for modelling was 163 unchanged (p≤0.05), whereas it was corrected for the interpretation of the multivariate models (p≤0.0016 164 $(\alpha=0.05 / 31 \text{ comorbiditiy groups}).$

All analyses were performed using SAS version 9.4. The comorbidome was created in Microsoft Excel
 2010.

167 **3. Results**

168 **3.1.BASELINE CHARACTERISTICS**

Patient characteristics for the entire cohort and stratified for initial cancer-related treatment regimen are presented in Table 1. Around two-thirds of patients were male and lived in urban areas, overall and in all treatment subgroups. At time of first lung cancer diagnosis, the average age was 67.0 years in the subgroups SU and CH/RA and 74.4 years in NT. Similarly, the EI score was almost the same in SU and CH/RA, but higher in NT. Metastasis status at baseline revealed notable differences between the three strata, with 41.4% of SU but 70.1% of CH/RA and 41.4% of NT. Accordingly, survival was shortest in NT and longest in SU.

176 3.2. PREVALENCE OF DISTINCT COMORBIDITIES

177 Due to the prevalence <5% and no significant association with survival (p>0.05%) no results are

178 presented for 'Peptic Ulcer Disease excluding bleeding', 'Psychoses', 'Lymphoma', 'Drug Abuse', 'Blood

179 Loss Anemia' and 'AIDS/HIV'.

180 Contrasting prevalence between SU and CH/RA revealed similar proportions for most comorbidity groups,

181 whereas some showed differences of more than 10%. We found higher proportions of 'Depression',

182 'Weight Loss', 'Other Neurological Disorders', and 'Paralysis' in CH/RA. In parallel, lower proportions

183 were shown for 'COPD', 'Cardiac Arrhythmias', 'Solid Tumor without Metastasis', 'Obesity', and

184 'Complicated Hypertension'.

185 Out of 22 comorbidity groups with more than 5% prevalence in the total cohort, 16 had the highest

prevalence within NT. The difference to SU respectively CH/RA was most pronounced (>30%) for 'Fluid

and Electrolyte Disorders', 'Cardiac Arrhythmias', 'Congestive Heart Failure', 'Renal Failure', 'Complicated

188 Diabetes', 'Weight Loss', 'Other Neurological Disorders', and 'Paralysis'. In contrast, we found that

¹⁸⁹ 'Obesity' had the lowest prevalence within NT. The data are presented in Table 2, 2nd, 5th and 8th column,

respectively, and visualised as areas within the comorbidomes in Fig. 1.

191 SA1 showed comparable prevalences of comorbidities within the three strata, with slightly higher

192 proportions within SU and CH/RA, and several slightly lower proportions within NT. Within all subgroups,

there was only a slight increase of comorbiditiy prevalence (<7%) in 'COPD', 'Solid Tumor without

194 Metastasis', 'Depression' and 'Weight Loss' (+2.6%, +4.3%, and 4.9%, respectively) (see Appendix Table

195 A.1, 2nd, 5th and 8th column, respectively).

196 3.3. COMORBIDITY AND SURVIVAL

197 Kaplan-Meier curves for grouped EI scores stratified by treatment regimen are shown in Fig. 2. We found

significant differences (p<0.0001) in survival between the EI score groups in the strata SU and CH/RA but

199 not in the stratum NT (p=0.08). Best prognosis was found in patients with SU and up to one comorbidity,

and worst in patients with NT and more than five comorbidities.

HRs indicated stratum-specific associations of comorbidities and survival (see Table 2). In general,

202 effects were small and tended to be larger in patients with cancer-related treatment, especially in those

who underwent surgery. Looking at the distinct HR within the Cox models adjusted for fixed covariates,

we found a higher number of significant negative associations within SU and CH/RA, compared to NT

205 (number of HR>1: 12, 10, and 6, respectively). Positive associations with survival were found for 2 (both

206 SU and CH/RA) and 4 (NT) comorbidities. The profiles of relevant comorbidities were similar for SU and

207 CH/RA, whereas that for NT was reduced and with an opposite direction for 'Depression' (from negative 208 within SU and CH/RA to positive within NT). Beside this, only within NT the two most prevalent 209 comorbidities 'Uncomplicated Hypertension' and 'COPD' showed a positive association with survival. 210 Extending to the multivariate model, all effects pointed into the same direction as in the 'univariate' ones, 211 but predictors for survival lost significance or showed reduced p-values, especially among SU patients. 212 The pre-fixed covariates predominantly showed a strong statistical impact. The negative association for 213 'Metastases at baseline' was strong in all three subgroups. Female gender presented a reduced risk for 214 mortality, which was also stronger within SU and CH/RA.

215 Contrasting the comorbidity impact between the distinct treatment regimen, only 'Weight Loss' and 216 'Paralysis' showed a significant detrimental association in all three strata. Within SU and CH/RA, 'Alcohol 217 Abuse', 'Other Neurological Disorders' and 'Coagulopathy' remained as additional negative predictors 218 and the positive impact of 'Lipid Metabolism Disorders' and 'Obesity' remained as well. A negative 219 association for 'Depression' and 'Pulmonary Circulation Disorders' was found only within SU. Within 220 CH/RA 'Fluid and Electrolyte Disorders', 'Congestive Heart Failure', 'Renal Failure' were additional 221 significant predictors. Again, within NT the comorbidity profile was different and also showed less 222 significant predictors. The most prevalent comorbidity 'Uncomplicated Hypertension' lost its protective 223 effect. Only in patients within NT a positive association of COPD with survival was shown, and, in contrast 224 to SU, 'Depression' was associated with a better prognosis. Further negative associations were found in 225 patients with 'Fluid and Eletrolyte Disorders' and 'Congestive Heart Failure', which were also shown within CH/RA. 226

Our results for prevalences and multivariate HRs of comorbidity groups are graphically presented in form of comorbidomes for subgroups of treatment regimen in Fig. 1. Here the specific patterns of negative and positive associations become obvious, particularly the similarity of SU and CH/RA.

230 3.4. SENSITIVITY ANALYSIS

231 Multivariate models within SA1 resulted in slightly different HRs within the treatment strata (see Appendix,

Table A.1) but we found a changed pattern of relevant comorbidities: Within SU, 'Fluid and Electrolyte

233 Disorders', 'Congestive Heart Failure' and 'Uncomplicated Diabetes' had an additional impact on

234 prognosis. Within CH/RA, 'Coagulopathy' was no longer a negative predictor for survival. Within NT, we 235 found an additional positive association with survival for 'Lipid Metabolism Disorders', 'Solid Tumor 236 without Metastasis', and 'Valvular Disease', and a negative impact in patients with 'Coagulopathy', 237 whereas 'Congestive Heart Failure' showed no longer a significant association. 238 After Bonferroni-Adjustment (SA2), 'Weight Loss' was the only covariate showing a significant association 239 within all treatment strata. 'Paralysis' remained as another predictor only within SU and CH/RA. Survival 240 of patients within SU was additionally associated with 'Pulmonary Circulation Disorders' and 241 'Coagulopathy'. 'Fluid and Electrolyte Disorders' maintained their negative impact on survival both within

. .. -

CH/RA and NT (see Appendix, Fig. A. 2).

243 4. DISCUSSION

242

244 In this cross-sectional analysis of 16,202 incident lung cancer patients, comorbidities were of high 245 prevalence and frequently showed a negative association with 5-year survival. As highlighted within the 246 comorbidomes, comorbidities related to shorter survival tended to be of lower prevalence, whereas highly 247 prevalent comorbidities mostly did not show any association with survival. Comorbidity burden differed by 248 initial cancer-related treatment regimen and did not show a consistent shift in proportions: By trend, 249 comorbidities were more frequent in patients without treatment, however some had the highest 250 prevalence within the surgery-group. Within each treatment group, 'Weight Loss' and 'Paralysis' were the 251 strongest negative predictors for survival. 'Lipid Metabolism Disorders' and 'Obesity' showed positive 252 associations. As a general finding, the additional effect of comorbid conditions on survival was small and 253 more pronounced among treated patients, whereas the additional impact of comorbidity burden remained 254 low among patients without treatment.

A comparison of comorbidity burden across different studies is a sensitive issue, as comorbidity is measured differently and mostly preselected patients come from various settings. However, this can be done at least for established comorbidities within population-based studies with consideration of the different context. These show a high burden of comorbidity, especially for elder male patients [3, 8, 9]. The most frequent concomitant diseases are 'COPD', 'Cardiovascular Diseases', 'Peripheral Vascular

Disease', 'Hypertension', 'Congestive Heart Failure', 'Diabetes' and 'Renal Disease', and 'Weight Loss' if
 investigated.

262 Findings in lung cancer patients in Nebraska showed a prevalence of 'Metastases' and 'COPD', that fitted 263 very well with our results (both about 50%, respectively), but 'Congestive Heart Failure' was of higher 264 prevalence within our study population (22%, and 13% in Nebraska) [9]. In comparison to Scottish lung 265 cancer patients, we found a similar prevalence for 'COPD' (43%, and 49% in Scotland), but a much lower 266 proportion of patients with 'Weight Loss' (9%, and 53% in Scotland) [8]. Contrasting our results with 267 reports from the Dutch cancer registry, prevalences were much higher for 'COPD' (43%, and 22% in the 268 Netherlands), 'Hypertension' (66%, and 12% in the Netherlands) and 'Diabetes' (29%, and 7% in the 269 Netherlands). These differences could be explained by a different classification of comorbidities, 270 especially the limitation to medically treated patients for 'Diabetes' in the Dutch study. Beside this, our 271 prevalences showed different proportions as a result of different assessment of comorbidities, both from 272 the timespan of our baseline and our inclusion criteria for diagnoses, considering both inpatient and 273 outpatient diagnoses. Restricting identification of baseline comorbidities to the guarter of lung cancer 274 diagnosis (SA1) resulted in higher prevalences for most comorbidities within SU and CH/RA, whereas 275 within NT comorbidities tended to be of lower prevalence with the inclusion criteria of SA1. These shifts 276 may be explained by additional outpatient diagnoses that could have occurred close to the lung cancer 277 diagnosis, which were recorded only once within the initial guarter of lung cancer and therefore were 278 missing within our main analysis. Patients within NT had a median survival of 2 months, which could have 279 influenced the reporting rate for diagnoses [22]. Thus, our analysis could have underreported those 280 comorbid conditions documented as a single inpatient diagnosis.

Among patients without lung cancer-related treatment in our study, the results for the prevalence of comorbidities met our expectations because this subgroup was older and thereby the general comorbidity burden was supposed to be higher. Unexpectedly, comorbidity burden was substantial as well among SU patients, even though surgery is mostly recommended for patients with higher performance status (i.e. those with less comorbid conditions). The higher proportions within surgery treated patients could also be the result of a different coding practice, i.e. because of a more precise documentation within certain circumstances [23].

The associations with survival within our study in general were small (HR: 0.86 up to 1.84), whereas other authors reported HRs beyond 2 or more [7, 9]. This could be the result of inclusion criteria for the sample and the strong association of the adjusting fixed covariates 'Female gender' and 'Metastases at baseline', which were the strongest predictors for survival. We found similar HRs within SA1, but by trend more comorbidities showed associations within the multivariate models, noteworthy within NT. In contrast, within SA2 we found a remarkably reduced picture of categories, which could be useful impact for further investigations to improve the treatment of lung cancer patients.

295 Although they are not included within the EI we examined 'Lipid Metabolism Disorders' due to their high 296 prevalence in our cohort. Here, we found an association with longer survival in patients with SU and 297 CH/RA. Other studies found that patients with 'Lipid Metabolism Disorders' treated with statins had a 298 better survival prognosis. Therefore, although we did not distinguish between treated or untreated 299 comorbidities, this could be an explanation for our result [24]. Similar to other studies, we found that 300 'Obesity' was a predictor for improved survival [25], whereas 'Weight Loss' was associated with worse 301 survival [26]. This effect is known as the "obesity paradox", which states that obese patients are at a 302 higher risk of developing certain diseases, but increased body weight also leads to a better prognosis due 303 to greater physiologic reserves. Further, we found that COPD has a protective effect within NT. This could 304 be a result of lead-time bias by an earlier detection of lung cancer. However, in this context, it is 305 surprising to see this effect in the NT group [9].

306 The role of some conditions in terms of concomitant disease vs. sequelae is ambiguous. 'Coagulopathy' 307 could be an independent comorbid condition as well as a complication of chemotherapy [27]. 'Other 308 Neurological Disorders' might be the result of metastases, while they also might exist as a comorbid 309 condition per se [28]. In this context it needs to be considered, that some EI conditions are known to be a 310 symptom of cancer cachexia. Extreme 'Weight Loss' is a result of metabolic changes during cancer and is highly related to 'Fluid and Electrolyte Disorders' and 'Lipid and Metabolism Disorders' [29]. Together with 311 312 'Depression' these categories could be considered as severity indicators rather than as concomitant 313 comorbidities in lung cancer patients.

Beyond this, some comorbidity groups may act as competing risk factors or a risk modifier. 'Paralysis' is a symptom of stroke, which was found for about one third of patients with this comorbidity, but it may also

316 be a side effect of chemotherapy or the result of metastases affecting the neurological system. We 317 controlled both for chemotherapy and the presence of metastases, which are associated with the severity 318 of cancer. Thus, it seems that complications resulting from immobility itself may lead to a worse survival 319 prognosis, e.g. the development of emphysema that is known to be crucial for the survival prognosis. 320 Apart from the sensitive issue of interpreting comorbidity comprehensively, the following caveats exist: 321 We did not have information on cancer stage or cancer histology in our data. Both stage and histology are 322 known to be the strongest predictors for survival [30], and previous studies substantiated evidence that 323 the effect of comorbidities on survival varies by stage [8, 31]. However, we believe that by stratification on 324 treatment regimen and adjustment for baseline metastases we addressed this issue in the best possible 325 manner.

The treatment of a comorbidity itself probably influences survival, but, some comorbid conditions are likely mutually reinforcing. Given recent evidence on an enhanced mortality effect of combined ILD and lung cancer [32, 33], it seems justified to assume corresponding interactions for other conditions as well. However, we did not include interaction-terms between comorbidities in order to keep the information obtained interpretable in a straightforward manner.

331 Despite these drawbacks, we assessed the first lung cancer comorbidome for Germany, by applying a 332 rather exhaustive assessment of comorbid conditions. We accounted for inpatient and outpatient 333 diagnoses and screened a period of six months before the initial lung cancer diagnosis for corresponding 334 diagnoses. Therefore, our results for comorbidity burden are expected to be representative for a routine 335 care setting and might be less prone to strategic coding decision during the immediate period around the 336 lung cancer diagnosis. Moreover, we added highly prevalent conditions by amending the established EI 337 with 'Lipid Metabolism Disorders'. Thus, we were able to show a very comprehensive picture of baseline 338 comorbidity burden in lung cancer patients.

We had access to a large number of incident lung cancer patients within the German Statutory Health Insurance System. Baseline characteristics of our sample are comparable to results from the populationbased lung cancer report for Germany [34]. Thus, we believe our results are representative. Our study has all advantages of health insurance data, having only minimal selection and no recall bias as well as

minimal possible loss to follow-up. Further, our study is multicentered as it was based on information of
 health care providers within whole Germany, painting a reliable picture on comorbidity structures and
 treatment options within a representative population. We therefore believe that we gave maximal
 consideration of comorbidities among incident lung cancer patients which are transferable beyond the
 German SHI context.

348 5. CONCLUSION

349 Investigating the impact of comorbidity on survival in lung cancer patients, we found specific comorbidity

350 profiles among distinct treatment regimens. Despite by trend detrimental effects on survival some

351 comorbid conditions showed a positive association. Our analysis thus not only supports the previously

described 'Obesity paradox', but especially points out the crucial role of 'Lipid Metabolism Disorders',

353 which is coming up as a hallmark within recent cancer research [24, 29]. To further elucidate the

354 mechanisms beyond the beneficial impact of 'Lipid Metabolism Disorders' a closer look on their treatment

355 - particularly with statins - is highly recommended to optimize treatment decisions in lung cancer

356 patients.

- 357 ACKNOWLEGDEMENTS
- 358 We are grateful for the input of Ulrike Nimptsch about the adaption of the coding algorithm for the
- 359 Elixhauser Comorbidity Index to the German Modification. We also like to thank Werner Maier for
- 360 supporting the analysis of district areas and Rolf Holle for comments and suggestions that improved the
- 361 development process of the analysis.
- 362 Data for this study was provided by the AOK Research Institute (WIdO, data owner). A contract between
- the data owner and the academic researchers ensures that the latter have the full scientific responsibility
- 364 combined with the right to publish the results.
- 365 CONFLICT OF INTERESTS
- 366 The authors declare that they have no competing financial or personal interests.
- 367 FUNDING
- 368 This research did not receive any specific grant from funding agencies in the public, commercial, or not-
- 369 for-profit sectors.
- 370

Caption Figure 1

Fig. 1

Lung Cancer Comorbidome by initial cancer-related treatment regimen. Graphic expression of comorbidities with more than 10% prevalence in the subsample or comorbidities with the strongest association with survival [hazard ratio (HR) with p≤0.05] within stratified multivariate models (adjusting for age, sex and metastases at baseline). The area of the circle relates to the prevalence of the disease. Comorbidities with a statistically significant decrease in survival (HR>1) are fully inside the dotted orbit, their proximity to the centre (death) expresses the strength of the association between the disease and risk of death (1/HR). Those comorbidities with a statistically significant association with survival.
