Abstract. Most machine learning algorithms require that training data are identically distributed to ensure effective learning. In biological studies, however, even small variations in the experimental setup can lead to substantial deviations. Domain adaptation offers tools to deal with this problem. It is particularly useful for cases where only a small amount of training data is available in the domain of interest, while a large amount of training data is available in a different, but relevant domain.

We investigated to what extent domain adaptation was able to improve prediction accuracy for complex biological data. To that end, we used simulated data and time-lapse movies of differentiating blood stem cells in different cell cycle stages from multiple experiments and compared three commonly used domain adaptation approaches. Results showed that *EasyAdapt*, a simple technique of structured pooling of related data sets, was able to improve accuracy when classifying the simulated data and cell cycle stages from microscopic images. Meanwhile, the technique had minimal negative impact on the classification accuracy, which is common in other techniques that build models with heterogeneous data. Despite its implementation simplicity, *EasyAdapt* consistently produced more accurate predictions compared to conventional techniques.

Domain adaptation is therefore able to substantially reduce the amount of work required to create a large amount of annotated training data in the domain of interest necessary whenever the domain changes even a little, which is common not only in biological experiments, but universally exists in almost all data collection routines.

Keywords: Transfer learning · Domain adaptation · EasyAdapt · Batch effect

1 Introduction

Over the last decade, machine learning, especially supervised learning, has become increasingly important in biological and medical research. Example applications range from protein structure prediction [1] and the identification of new disease subgroups from gene expression data [2], to the identification of cell connectivity [3] and the prediction of phenotypes from time-lapse [4] data and high throughput imaging [5]. With improving capabilities of data collection and growing computational resources, machine learning will be playing an even more important role in understanding of underlying biological processes.

One of the most well-known limitations of supervised learning, however, is the need for a large amount of annotated data. In biological and medical research, this requirement is often difficult to meet, as it necessitates expert knowledge and intensive manual work. With an increase in high-throughput data it becomes more and more unrealistic to annotate all observations. An appealing alternative is to combine already-annotated data from one or multiple sources in order to build a model for a new problem for which there is only little annotated data.

Another limitation of classic supervised learning techniques is the poor performance in dealing with data from multiple sources. A typical problem in biological research are batch effects. Batch effects describe qualitative changes in measurements because of experimental changes that are unrelated to the biological feature under investigation [6]. Typically, differences in the experimental setup, the use of different protocols, reagents or different machine settings can all lead to such effects. Conventional machine learning techniques are less effective in data with batch effects, due to differences in underlying distributions. Even in the case of an experiment being designed to be a replicate, the classifier trained with data from one experiment often tends to have lower predictive accuracy when applied to data from another replicate [7]. While it is possible to build a new model using only data from one experiment, this would mean wasting expert knowledge and involve labor-intensive annotation for each separate experiment. Consequently, it is desirable to have a model that can achieve a high performance with limited additional annotation work.

Domain adaptation describes the case where at least a part of the data used to train a model follows a different distribution from the data on which the model is finally applied [8]. It is closely related to the notion of transfer learning and multitask learning [8,9,10]. We follow Pan and Yang [9] and consider transfer learning as the more general term, with domain adaptation being one special form of transfer learning. Domain adaptation can be applied where a large number of annotated data are available in one or more domains that are not of direct interest (the source domain), while only a limited amount of annotated data is available in the domain of interest (the target domain) (Fig. 1). The idea of domain adaptation is to transfer the knowledge from the source to improve the learning in the target domain. Technically, it can be understood that the pre-trained decision boundary only requires some 'minor' tuning from a smaller amount of data to be applied to the new domain. Domain adaptation techniques have originally been developed to address text classification problems [11,12,13].

Domains in this context correspond to different types, styles or topics, e.g., a model trained with news articles can be adapted to classify a corpus containing fiction texts [12]. However, the concept is very broad and can be applied to any variable that is likely to lead to differences in the data distribution, e.g. different machines, protocols or reagents. Here, we consider domains representing different replicates of a biological experiment, where each replicate can be seen as a different domain.

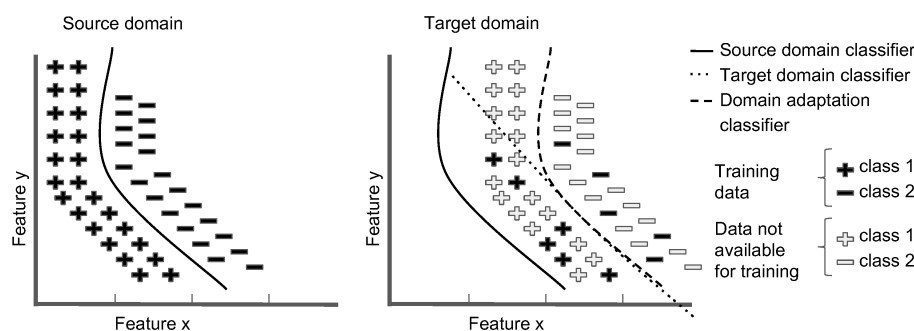

Fig. 1. Illustration of a domain adaptation classifier in the target domain that leverages knowledge from a related, but different problem in the source domain. A direct application of the source domain (left) classifier (solid line) would lead to a poor classification in the target domain (right). On the other hand, using only data available in the target domain to train a target domain classifier (dotted line) would also lead to poor performance, as the available data is not sufficient to fully learn the decision boundary. Transferring the knowledge from the source to the target domain using domain adaptation leads to an enhanced classification performance.

2 Methodology

2.1 Definitions

We define a domain D as a feature space X with the marginal probability distribution $P(X)$ and a label space Y . A function $f(\cdot)$ maps x_i to y_i , where $x_i \in X$ and $y_i \in Y$. We consider problems with an arbitrary number of source domains D_{s_1}, \dots, D_{s_m} ($m \geq 1$) and a single target domain D_t . For a multi-class classification problem, we convert to a set of binary classification problems in a one-vs-all manner, i.e. by training a single classifier per class, with the observations of that class as the positive examples and all other observations as negative examples. The aim of domain adaptation is to use the knowledge from the source domains and limited labeling information from the target domain to effectively learn the objective predictive function $f(\cdot)$ for the target domain.

2.2 Learning techniques

We compare a particular domain adaptation algorithm, the *EasyAdapt* technique [14], with four more conventional techniques of building classifiers. We refer to these as the '*Source*', '*Target*', '*Combined*' and '*Domain*' techniques. In this study, all domains share the same feature space X . In general, the techniques require a common feature subspace across domains. The details of these techniques are outlined below and illustrated in Fig. 2. For all techniques, we assume that the number of observations in the source domains is sufficiently large to estimate a model that will generalize to unseen data from the same distribution. In the *Source* technique, we only use labeled data from the source domains D_{s_1}, \dots, D_{s_m} to train the model. The model trained on the source domains is then evaluated on data from the target domain, giving an indirect measure of proximity between source and target domains. In the *Target* technique, we only use labeled data from the target domain D_t to train the model, without considering the data from the source domains. Given enough training data in the target domain, this model should perform the best. In the *Combined* technique, we use labeled data from both the source and the target domains without any reference to the domain membership when training the models (where every data point is weighted equally). This is arguably one of the most common approaches in practice [15,16,17], where a typical scenario consists of a relatively large amount of labeled data from the source domains and a limited amount of data from the target domain. In the *Domain* technique, we slightly adapt the *Combined* approach. An additional set of binary variables encoding the domain membership is added as a new feature set [18]. It is expected to enable the estimated function to have a different offset for each domain, while making use of all the other predictors from all domains to define the shape of the function in common. The *EasyAdapt* domain adaptation technique [14,19], uses a simple transformation to create a representation for the general data structure common to source and target domains and a separate representation for each domain. In principle, *EasyAdapt* can be applied to an arbitrary number m of source domains D_{s_1}, \dots, D_{s_m} and a single target domain D_t . However, it is required that the number of features per domain is not too large, because the feature space is increased up to $\mathbb{R}^{(m+2)p}$ dimensions with p being the dimension of the shared feature space. Features only available in the target domain could also be incorporated by setting the relevant entries for the other domains to 0. The technique is simple and flexible and can be used with any supervised classifier.

3 Results

3.1 Simulation study

To test the performance of the different techniques, we created a two dimensional artificial data set with one source domain and one target domain (each with 200 data points), where the ground truth is known (see Fig. 3A). 15% of the data in the target domain was used for training. The remainder of data in

Fig. 2. Schematic overview over the different learning techniques. We denote the feature matrices with x_{s_1} to x_{s_m} for the m source domains and with x_t for the target domain. Label vectors are denoted by y_{s_i} and y_t , respectively. Single underlined zeros and ones are column vectors, while double underline indicates matrices of dimensions matching the dimensions of x_i . The *Domain* technique is adding an additional feature encoding the domain membership in the form of a one-hot encoding, where the k th domain is encoded via a 1 at position k . The *EasyAdapt* technique creates both a unified representation of the data across all domains (analogously to the *Combined* technique) and a separate representation for each domain (diagonal entries).

the target domain was used for performance evaluation. Support Vector Machine (SVM) [20,21] with a radial basis function (RBF) kernel was chosen as the basic classifier for all the five learning techniques described in the previous section. Parameters were selected using a grid search with 5-fold cross-validation. From both the contour lines (Fig. 3B-F) and the ROC curves (Fig. 3G) it is evident that the *EasyAdapt* technique captured the distribution of the target domain most accurately (AUC = 0.91), by leveraging information from both the source domain and the limited amount of training data from the target domain in building the classifier. Fig. 3B illustrates that due to the limited amount of training data in the target domain, the *Target* technique (AUC = 0.86) learned a decision boundary that was much more complicated than the underlying distribution. The *Source* technique (AUC = 0.55, Fig. 3C) directly applied the decision boundary learned from the source to the target domain, leading to an evident discrepancy with respect to the target domain distribution. The *Combined* technique (AUC = 0.64, Fig. 3D), shifts towards the target domain when building the model. Due to the comparatively large number of source domain data, however, the model is strongly biased towards the source distribution. The *Domain* technique (AUC = 0.89, Fig. 3E) learned a model that describes the target domain quite well, especially in regions close to the centre. In regions that were farther away, however, the contour lines were clearly distracted by source domain information. Compared with these four techniques, the *EasyAdapt* technique (Fig. 3F) learned a model that described the target distribution the best, by successfully integrating the information from the two domains.

3.2 Imaging data set

For a realistic evaluation case, we applied the techniques to a biological data set [23] consisting of 2888 cells with 186 cell texture and shape features from time lapse microscopy experiments, where 8 different cell cycle stages have been

6 M. Schneider et al.

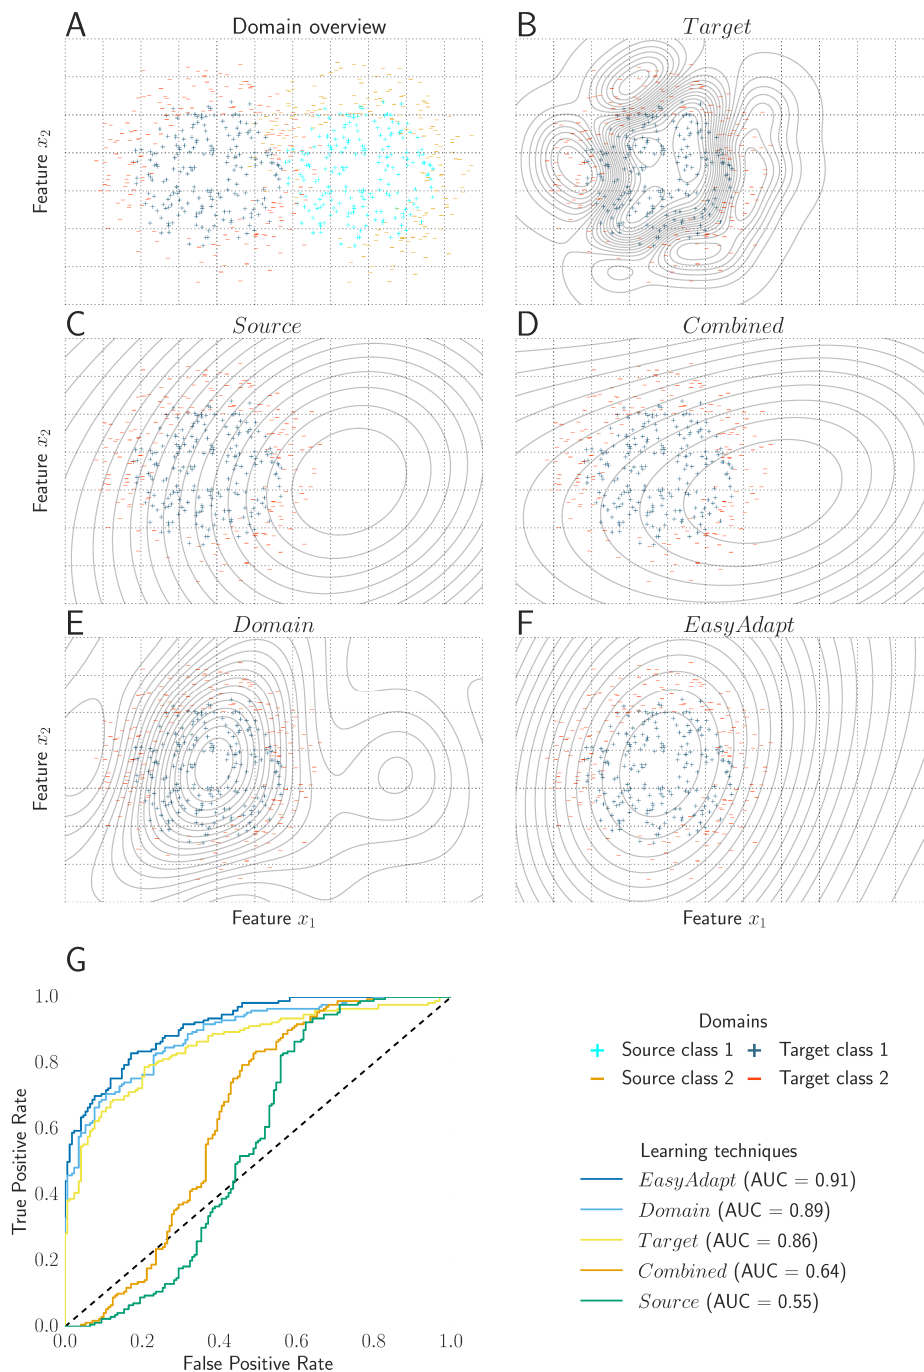

Fig. 3. *EasyAdapt* separates classes best on simulated data. (A) Distribution of the two classes in the source (light blue and orange symbols, right) and target domain (blue and red symbols, left). The target domain was divided into a training set and a test set. The target training set consisted of 15% randomly sampled data from the target domain. Classifiers were trained using RBF kernel SVM. (B-F) Classifiers created using *Target* (B), *Source* (C), *Combined* (D), *Domain* (E) and *EasyAdapt* (F). Contour lines represent different thresholds of the decision boundary of the corresponding classifier. (G) ROC curves for the different techniques.

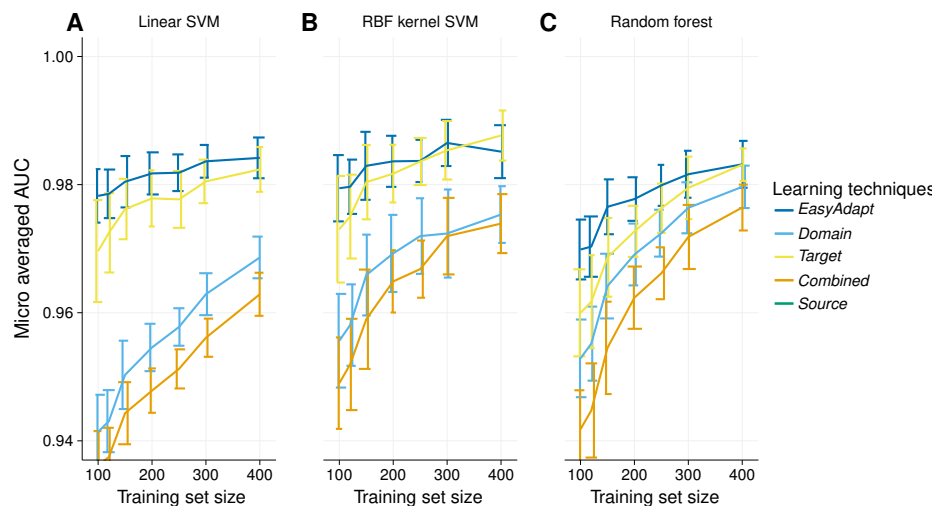

Fig. 4. *EasyAdapt* outperforms other techniques in particular for small training set sizes. Performance for (A) linear SVM, (B) radial basis function (RBF) kernel SVM, and (C) random forest classifiers for learning with experiments 1 and 3 as source domains and experiment 2 as the target domain. Performance is measured as micro-averaged AUC (mean \pm standard deviation, $n=50$ iterations) [22]. We do not plot the *Source* technique since it is independent of the training set size.

manually annotated. The data comes from three experiments, with 1468, 726, and 694 cells, respectively. It is important to note that the experiments differ regarding the microscope objectives and the magnification factor (10x for experiments 1 and 3, and 20x for experiment 2) used, and were conducted by different lab technicians [23]. The different techniques were trained and tested in a one-vs-all manner on the 8 cell cycle stages (where each stage is treated as a separate class). We always picked two experiments to represent the two source domains and the remaining experiment as the target domain. All data from the source domains together with the data from the target train set were centered and scaled to unit variance. Subsequently, we applied a principal component analysis (PCA) to the data, (i) keeping only factors explaining 98% of variance (reducing the number of features to roughly 20-30), and (ii) keeping only the 16 highest loaded principal components. We used 4-fold cross-validation and a grid search to select parameters and subsequently evaluated performance on a test set in the target domain. The procedure was repeated 50 times for different target training set sizes of 100, 120, 150, 200, 250, 300, and 400 samples in order to obtain robust estimates for variable performance, especially when using small training set sizes. Independent of the amount of data available in the target domain, we used a fixed-sized test set with 240 samples for performance evaluation, which was randomly chosen for every iteration and for every new training set. In order to evaluate and compare performance of techniques, we chose the micro-averaged AUC. Using this metric, class imbalances were taken into account by

computing cumulative values for true positives, false negatives, true negatives and false positives for every label and then computing the performance measure from the aggregated values [22]. We compared three different base classifiers, namely a linear SVM [21], an RBF kernel SVM [20], and a random forest classifier [24].

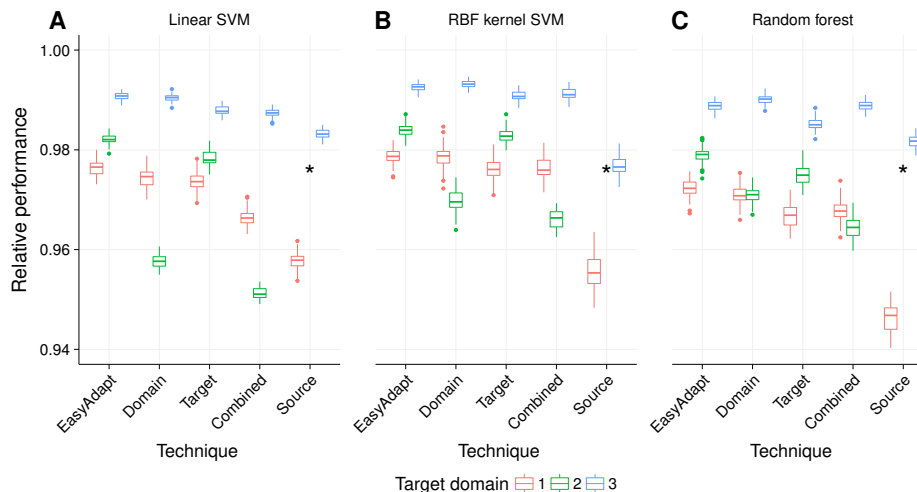

Fig. 5. Relative performance, measured as area under the curve for each of the 50 iterations that were used to generate the average performance lines in Fig. 4. Each data point shows performance over the range of training set sizes (100-400) for one iteration of the target domain; each box plot comprises data from 50 iterations. Performance is shown for (A) linear SVM, (B) radial basis function (RBF) kernel SVM, and (C) random forest classifiers.

We found that the *EasyAdapt* technique is particularly robust when working with a small set of training samples in the target domain and consistently performed among the top techniques in the regime of small training set sizes (Fig. 4). As expected, with increasing training set size the *Target* technique catches up and for 400 training samples (the maximum training set size in the study), the performance for this technique was among the best performing techniques. In general performance improved for all techniques with increasing training set size with exception of the *Source* technique, which was not trained with any of the target domain data. Results from all experiments are summarised in Table 1, showing the performances of the five learning techniques across three different base classifiers, two different feature selection methods and three different target domains (each combination of a base classifier, a feature selection method and a target domain is referred to as a setting below).

To assess performance of the different techniques across training set sizes Fig. 4, we measured the area under the curve for each of the 50 iterations for a

given setting. This renders an aggregated performance for each train/test split across the range of training set sizes we used and gives us an estimate of performance for small to medium training set sizes. In contrast to the micro-averaged AUC across different training set sizes, this measure takes into account the fact that we tested more smaller training set sizes (in the range of 100-200 samples) and is a more conservative measure than simple averaging in our case. This is achieved by weighting performance according to train set size sampling frequency. Additionally, we normalized performance, so that a perfect classifier would achieve an relative performance of 1, corresponding to an AUC of 1 for all training set sizes in the range from 100 to 400 samples. Fig. 5 shows the distribution of this performance measure for different techniques, classifiers and transfer directions. Across all settings, the *EasyAdapt* technique consistently showed superior performance over other techniques: Among 18 different settings, *EasyAdapt* ranked 15 times the best or tied for the best and 3 times as the second best. This not only demonstrates the effectiveness of knowledge transfer of *EasyAdapt*, but also shows its generality with respect to base classifiers and feature selection methods under different transfer situations. The second best technique was the *Domain* technique, with 8 times the best or tied for the best and 3 times in the second place. This indicated that in many cases the membership feature used by the *Domain* technique was also able to leverage some knowledge from related domains. The technique with the lowest performance was the *Source* technique, which ranked last in every setting.

In practice, it is hard to predict whether pooling of data will actually improve prediction performance or lead to negative transfer, i.e. learning in the target domain might be negatively affected by the use of additional information, if domains are too different [9,25]. An example for such negative transfer is the case of experiment 2 as the target domain. Here, both the *Combined* and *Domain* techniques performed considerably worse compared to the *Target* technique (see Table 1). This can probably be explained by stronger differences in distributions between experiments 1 and 3 on the one hand, and experiment 2 on the other, as experiment 2 used a different magnification. This difference can also be seen from the extremely poor performance of the *Source* technique for experiment 2 as the target domain. It is worth noting that the negative transfer that affected the *Combined* and *Domain* techniques with experiment 2 as target domain appears stable across different training set sizes (Fig. 4). Importantly, we do not observe such negative transfer in the case of the *EasyAdapt* technique. Performance of *EasyAdapt* was comparable or even slightly better than the *Target* technique when looking at experiment 2 as the target domain.

4 Discussion

In the present study, we investigated whether accounting for experimental variation in biological data using a domain adaptation techniques can help improve prediction performance and reduce the need for labeled data. We show that indeed, given only limited training data, the *EasyAdapt* domain adaptation tech-

nique boosts prediction performance both in a simulation study and a data set of imaged single cells [23] and leads to more robust predictions in the presence of experimental variation.

Applications of domain adaptation techniques in biological research have so far been mostly restricted to genomic sequence analysis [26,27]. Widmer et al. [28,29] used a more general multi-task learning framework in conjunction with regularization based supervised learning methods, such as SVM and logistic regression for splice-site and binding site prediction and to transfer model parameters learned on 2D images to 3D images in order to enhance learning. In contrast to [29], we do not learn domain specific differences explicitly. In practice, this information is also often hard to quantify. Here, we rather focus on the effect of training set size and the pooling of heterogeneous data without quantitative knowledge about the relationship between domains. We compare performance of the *EasyAdapt* technique across three different machine learning algorithms. Furthermore, we consider a range of common ways of combining information from different domains, e.g. via explicit encoding of domain membership, a procedure that is often used in practice. We demonstrate that the *EasyAdapt* technique is relatively robust to negative effects of data pooling.

Our results have implications for dealing with biological batch effects in machine learning tasks and for improving learning in settings with limited training data, if additional source data is available. The *EasyAdapt* technique allows the reuse of existing data sets as source data and avoids cost-intensive manual

labelling of training data. Results confirm the problem that is one major motivation of this work: a model trained using data from one biological experiment is likely to have much inferior performance when applied to a different experiment, despite the experiments sharing similar experimental setups. Importantly, the *EasyAdapt* technique is general in that it does not change the machine learning method used and can therefore be applied to a wide set of problems. *EasyAdapt* strikes a balance between improving performance in cases when additional information is available and proofs robust to experimental variations. Compared with classic techniques such as the *Domain* and *Combined* techniques, the *EasyAdapt* technique is not affected by negative transfer and for small to medium training set sizes it can improve learning in the target domain.

The technique is limited by the necessity to identify domains, i.e. it is necessary to have domain knowledge about potential differences in experimental conditions and fundamental differences in feature distributions that define domains. Furthermore, it requires that the domains have a shared feature subspace and are distinct [14]. Both requirements are typically fulfilled in biological data. Further research will be necessary to develop empirical measures of domain relationships that help to identify cases where the use of domain adaptation in machine learning can be particularly helpful.
